## ACKNOWLEDGMENTS

The author gratefully acknowledges the sponsorship of his studies by the Air Force Institute of Technology. Materials and equipment were made available through Air Force Office of Scientific Research grant number 76-2955, without which this research could not have been completed. Thanks are expressed to Physical Electronics Industries, Inc., for equipment use and technical assistance in the AES/SIMS studies, and to the Rockwell Science Center for supplying a major portion of the vacuum system.

Appreciation is expressed to Carlos Arias for experimental assistance, to John Jeffries for obtaining roughness measurements, and to Professor Lyndon Taylor for provision of some of the vacuum equipment. Special thanks are extended to Professor Harris Marcus for many valuable suggestions and enlightening discussions.

## ABSTRACT

The effect of an oxygen environment on fatigue crack growth of Monel 404, commercially pure titanium, 2219-T87 and 7075-T651 aluminum alloys was investigated. Use of Auger Electron Spectroscopy and Secondary Ion Mass Spectroscopy indicated transport of the oxygen environment into the metal matrix coincident with passage of the fatigue crack. This evidence supports the theory of dislocation sweep-in of gaseous environments in the form of Cottrell atmospheres about the dislocations. For all materials tested, oxygen was shown to be transported during fatigue crack growth an estimated 125 to 600 Å deeper into the matrix than that observed strictly by diffusion. An increase in the growth rate for an oxygen environment compared to that in vacuum was observed for Monel 404 and titanium by a factor of approximately 5 and 2, respectively. Little increase in growth rate was apparent for the aluminum alloys. The increased growth rate can be explained as a result of reduced or modified plasticity in the matrix ahead of the crack tip due to the oxygen swept in. The change in local plastic behavior can lead to a smaller residual strain zone in the wake of the crack, reducing the portion of the cycle during which the crack closes on itself. The effective  $\Delta K$  consequently increases and crack growth rate necessarily increases.

## CHAPTER I

### INTRODUCTION

As industrial and scientific technology advances, there is an ever increasing demand on the materials scientist to develop more specialized and improved structural materials. While developing new materials, he also attempts to optimize use of presently available materials by characterizing the nature of failures in these materials, their response to types of loading, and their response to various environments. Through such studies, he is able to promote effective materials selection, improving structure lifetime and dependability.

One area of considerable interest, <sup>> studies of</sup> particularly ~~of~~ interest to the aerospace industry, is crack propagation under cyclic loading and environmental effects on the fatigue crack growth rate, <sup>are related. - p.40</sup> ~~^~~ The materials dilemma is epitomized in aircraft design, where weight and cost must be minimized but dependability and performance must be maximized. These clearly contradictory requirements can only be achieved if full knowledge of material response is known. The loading spectra of aircraft is such that fatigue damage is of primary concern and design must thus include consideration of environmental effects on fatigue crack growth rates.

Historically, design for fatigue damage has centered around statistical S/N data, where N is the number of cycles to failure and S is the cyclic loading stress level. With the inception of fracture mechanics theories, the S/N criteria is being replaced by  $da/dN$ , the crack growth per cycle, versus  $\Delta K$ , the crack tip stress intensity range, combined with the fracture toughness of the material,  $K_C$  or  $K_{IC}$ . The mode one stress intensity factor  $K_I$  is a function of the remotely applied load P, the crack length, a, and a geometry factor Y. For a compact tension specimen the relation can be expressed as [1]:

$$K_I = YPa^{1/2}/BW$$

where B is the thickness and W the width of the specimen. Geometric factors have been calculated for various dimensions of compact tension specimens. For fatigue tests, where the loading is cyclic, the range in stress intensity,  $\Delta K$ , is determined from the above equation by substituting  $\Delta P$  for P. Maintaining  $\Delta P$  constant during a test,  $\Delta K$  increases with crack length so growth rate is constantly increasing until the inherent fracture toughness of the material is reached. The plane strain fracture toughness,  $K_{IC}$ , is the K level at which unstable,

rapid crack growth occurs leading to failure of the component. The designer makes use of such data by assuming the presence of a flaw or crack of length determinable by nondestructive techniques and calculating the stress intensity. From the test data he then determines fatigue crack growth rate as a function of expected loading history and arrives at a good estimate of structure lifetime.

For experimental evaluation of environmental effects on crack growth, a desirable approach is to maintain a constant  $\Delta K$ , which should give a constant amount of damage in the front of the crack. An observed change in  $da/dN$  upon introduction of a new environment is then indicative of the environmental influence. The general effect of a gaseous environment such as water vapor, oxygen or hydrogen is to increase fatigue crack growth rate above that which occurs in the baseline inert gas or vacuum environment [2,3]. This "embrittling" nature of the environment may arise through an alteration of bonding strength at the crack tip resulting in premature decohesion.

Another possibility is that the environment is transported into the metal matrix ahead of the crack tip, decreasing or modifying the local plastic behavior of the matrix in this region, thus changing the crack closure

load in the crack closure model of Elber [4,5]. The crack closure concept consists of the well-documented fact that during part of the loading cycle, the crack closes due to a residual displacement pattern in the wake of the crack. This residual displacement arises from surface roughness and volume change due to the deformation. The resulting crack closure leads to loss of the singularity associated with the crack and the definition of an effective range in stress intensity,  $\Delta K_{\text{eff}}$ , which is calculated from the load range during which the crack remains open. The change in plastic behavior results in a smaller residual displacement in the wake of the crack, increasing the effective  $\Delta K$  and consequently increasing the growth rate.

The plasticity argument above depends on transport of the environment into the matrix to a much greater depth than diffusion would accomodate. A model for interstitial dislocation sweep-in has been proposed and applied to hydrogen [6,7], which indicates the plausibility of such transport, at least for a small atom like hydrogen. It is envisioned that since the region ahead of the crack tip is highly plastically deformed, with considerable dislocation production and motion, the environmental gases which adsorb and dissociate at the crack tip are picked up by dislocations as "Cottrell atmospheres" [8]. The

dislocations then carry the dissociated gases into the matrix until the atmosphere is stripped from the dislocation, or the dislocation becomes immobilized. Inherent to this transport model is reduction in plasticity ahead of the crack tip due to the drag force exerted on the moving dislocations by the solute atoms being swept along with them [9].

Problems arise, however, in an attempt to apply the mathematical model of transport to a larger atom, such as oxygen. The maximum penetration distance by dislocation transport based on the Tien, et. al., model [7] is given by:

$$X = \frac{DE}{kT(30b)^2f}$$

where D is diffusivity of the hydrogen in the lattice, E the dislocation/solute binding energy, 30 Burger's vectors the estimated hydrogen/dislocation interaction distance, and f the fatigue frequency. For oxygen, the binding energy is estimated to be 0.5 eV [10] and the interaction distance approximately 3 Burger's vectors. Using the above equation, for sweep-in of 100 to 1000 angstroms at room temperature and a cyclic frequency of 1 Hz, the oxygen diffusivity would have to be approximately  $10^{-15}$  to  $10^{-14}$  cm<sup>2</sup>/sec. Since diffusivity data for

oxygen in metals at room temperature indicates diffusivities more on the order of  $10^{-20}$  cm<sup>2</sup>/sec, sweep-in of oxygen by this model using the lattice diffusivity would be negligible. The diffusion rate near the surface could be enhanced by the less constrained configuration of this region, leading to faster diffusion of the interstitial oxygen. It is believed that oxygen may be transported into the matrix during the cyclic loading, offering an explanation of reported increased growth rate in an oxygen environment.

Since the sweep-in distance for dislocation transport of oxygen is expected to be extremely small, examination of this theory requires techniques which sample very thin surface layers, coupled with a means of etching the surface. These would provide a method of profiling oxygen concentration into a fatigue crack surface. A commonly employed method of gradual etching is inert ion sputtering, involving ionization of argon or other large inert gas atoms and accelerating these ions toward the surface of interest. Etching results from the ion/surface collisions, and the sputtered ions are mass analyzed with Secondary Ion Mass Spectroscopy (SIMS).

Another suitable surface technique is Auger Electron Spectroscopy (AES) which uses a focused electron

beam to excite atoms in the material under examination. In returning to their ground state, a percentage of the excited atoms undergo the Auger process which, simply stated, is the ejection of an outer shell electron having an energy directly related to the element involved [11]. This characteristic energy is maintained only if the electron avoids inelastic collisions in the matrix, leading to escape depths of unperturbed Auger electrons on the order of 5 to 20 Å.

SIMS gives direct mass information about all atoms being removed from the surface and is capable of differentiating between isotopes such as the oxygen-16 and oxygen-18 used in this study. AES provides elemental analysis of that which remains on the surface in a region covered by a focused electron beam about 5  $\mu\text{m}$  in diameter for this study, much smaller than the inert ion beam size of about 0.5 mm. The following sections describe experiments performed using these complementary techniques to determine if oxygen concentration in the metal matrix is in fact enhanced during growth of a fatigue crack.

## CHAPTER II

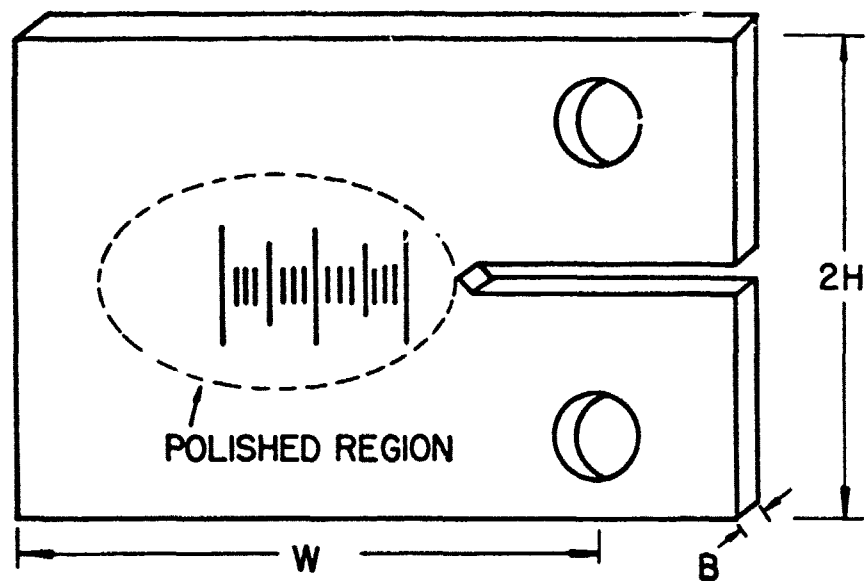

### EXPERIMENTAL PROCEDURE

#### Fatigue Crack Growth

Compact tension (CT) specimens of the geometry shown in Figure 1 were machined from as received plate stock. Materials tested were Monel 404\*, commercially pure titanium, and aluminum 7075-T651 and 2219-T87 alloys. Nominal compositions of the materials tested and  $\Delta K$  levels used are given in Table 1. Preliminary fatigue crack growth experiments were carried out in commercially pure oxygen as the test environment. The results were promising, however it was decided that use of an oxygen isotope might clarify the SIMS results by differentiating between oxygen transported during fatigue and that present from material manufacturing and recontamination during the experiments. The isotope oxygen-18 was obtained as 99.9% pure from Monsanto Corporation. The CT specimens were metallographically polished on one side in the region of crack propagation. Scribe marks were made on the polished surface at 0.16 cm intervals for visual measurement of crack length during cycling. Prior to installation in the test chamber, the specimens were

cleaned in acetone and methanol.

An all metal, bakeable, ion pumped vacuum system was assembled to accept the CT specimens. The system was installed in an MTS closed-loop electro-hydraulic test frame for fatigue cycling through metal bellows. Rough pumping was accomplished by two zeolite absorption pumps through a bakeable valve to the chamber. The same absorption pump was always used as the first rough pump to trap normally unpumpable gases through rapid volume flow carrying these gases into the pump, the pump then being quickly valved off to prevent back streaming of the gases which zeolite will not trap. This step brought the chamber pressure to the 50 to 100 micron range. The cleaner second absorption pump was then opened to the chamber to bring the pressure down to 10 microns or less, at which time it was valved off and the ion pumps were opened to the chamber. Bakeable valves also separated the bottled oxygen-18 and the two 8 l/sec ion pumps from the chamber. A 1.2 meter length of copper tubing between the valve on the oxygen bottle and the bakeable valve at the chamber provided a pre-chamber to control oxygen input to the chamber without a metered leak valve. The valve to the copper tubing was open during pumping and the tubing was heated to desorb gases, insuring transfer of pure oxygen-18 when needed.

Figure 2(a) shows a schematic of the pumping system, capable of pressures below  $1.3 \mu\text{Pa}$  ( $10^{-8}$  Torr). The actual assembly is pictured in Figure 2(b).

With the pressure below  $1.3 \text{ mPa}$  ( $10^{-5}$  Torr), the sample was cyclically loaded to initiate the crack at the starter notch and to grow the crack to a length of 2.54 cm from the load line, the beginning of the gauge section used. In the interest of time, the starter crack was begun using a higher  $\Delta K$  than the experimental value.  $\Delta K$  was reduced to the experimental level sufficiently early for the crack to grow well beyond the plastic zone created by the higher  $\Delta K$  before reaching the gauge section. This was done to prevent overload retardation [12,13] of the crack at the beginning of the experiment.

To maintain  $\Delta K$  constant, it was necessary to reduce the load as crack length increased. This load shedding was accomplished at crack length intervals of 0.16 cm which maintained  $\Delta K$  within approximately 6% of the desired value. The method of load shedding resulted in a  $\Delta K$  variation, giving rise to small retardation effects and consequently some scatter in crack growth rate data.

After the chamber pressure had dropped below  $13 \mu\text{Pa}$  ( $10^{-7}$  Torr), the fatigue crack was extended 0.8 cm

DIAGRAM OF TEST CHAMBER  
PUMP SYSTEM.

(b) PICTORIAL OF  
CHAMBER AS INSTALLED  
IN FATIGUE TEST FRAME

(b)

by sinusoidal loading at a frequency of  $10 \text{ sec}^{-1}$ . Fatigue crack growth rate in vacuum was established during this extension by shedding load at each 0.16 cm scribe line and noting the number of cycles required to extend the crack to each line. The ion pumps were valved off and the oxygen isotope was introduced into the chamber to a pressure of 10 kPa (1 kPa for 2219 aluminum due to limited supply of the isotope). Cyclic frequency was reduced to  $1 \text{ sec}^{-1}$  and crack growth rate in oxygen at constant  $\Delta K$  was established through fatigue crack extension of 0.8 cm as before. Since growth rate in vacuum is independent of frequency in this frequency range, a higher frequency for vacuum could be used in the interest of time. It should also be noted that during crack extension in the isotope environment, the vacuum fatigue surface was exposed to the isotope but plastic deformation occurred in the vicinity of the crack tip and not along the surface formed in vacuum. This results in the fracture surface grown in vacuum being exposed to the isotope longer than the region fatigued in oxygen-18. In addition both regions were exposed to ambient oxygen the same time when transported to the AES/SIMS system.

Upon termination of the fatigue crack growth, the chamber was backfilled to atmospheric pressure with argon or nitrogen and the sample was removed. Segments of the

specimen were then cut for examination in the combined AES/SIMS system. Their size was made compatible with the system, such that each segment was from the fatigue crack surface formed in either vacuum or the oxygen environment. Cutting was done slowly with a hacksaw to prevent enhanced diffusion through heating. The samples were sealed in glass tubes evacuated to 0.13 mPa ( $10^{-6}$  Torr) until AES/SIMS analysis was begun at the Physical Electronics Laboratory in Eden Prairie, Minnesota.

#### Sample Analyses

Additional samples of Monel and titanium were prepared by metallographically polishing through 0.05 micron diamond paste, then allowing them to oxidize in ambient air. These samples were for examination of roughness effects and to calibrate the ion sputtering rates as described later. The polished and the fatigue samples were ultrasonically cleaned in acetone and freon and mounted in the AES/SIMS system. A sample of tantalum with a  $Ta_2O_5$  layer of thickness known to be  $1000 \text{ \AA}$  was also mounted. The system was not baked, to avoid enhanced diffusion in the samples. Within a few hours the chamber pressure was pumped to the 0.13  $\mu$ Pa ( $10^{-9}$  Torr) range and analysis was begun. Argon was backfilled to a pressure of 2.6 mPa ( $2 \times 10^{-5}$  Torr) and

all electronic parameters were adjusted. An approximate sputter rate calibration of  $70 \text{ \AA}^{\circ}$  per minute was made by noting the time necessary to sputter through the  $1000 \text{ \AA}^{\circ}$  layer of  $\text{Ta}_2\text{O}_5$ .

The other samples were in turn rotated into analysis position. The sputter-ion gun was turned on simultaneously with the detectors and recorders, thus producing simultaneous plots of AES oxygen signal and negative SIMS mass 18 signal versus sputtering time. AES signals for other elements and a range of SIMS signals from mass 14 to 20 were monitored.

The fatigue samples were examined in a scanning electron microscope and photographs were taken to observe differences in fracture morphology for the two environments. A Bendix profilometer was used to obtain RMS roughness measurements of the fracture surfaces.

## CHAPTER III

### RESULTS

Growth rate data from the fatigue experiments is shown in Table 2. The factor of increased growth rate in oxygen over that in vacuum is indicated by the ratio of environmental growth rates. The aluminum alloys show little increase in growth rates, while Monel and titanium are very susceptible to increasing crack growth rates in the oxygen environment.

Figures 3 through 10 depict the data from AES and SIMS profiles, reduced as described later, to present the information in clarified form. In each case, oxygen concentration is extended deeper into the materials for the fatigue crack propagated in an oxygen environment. The profiles of the vacuum segments may be considered as normal diffusion oxide profiles since no plastic deformation occurred in this region during exposure to oxygen. As noted before, oxygen was exposed a longer time to the surface formed in the vacuum environment than that formed in oxygen. The evidence suggests a thicker region of enhanced oxygen level present for the samples where the crack was grown in oxygen, which is consistent with dislocation transport of oxygen during the plastic deformation associated with the fatigue crack propagation.

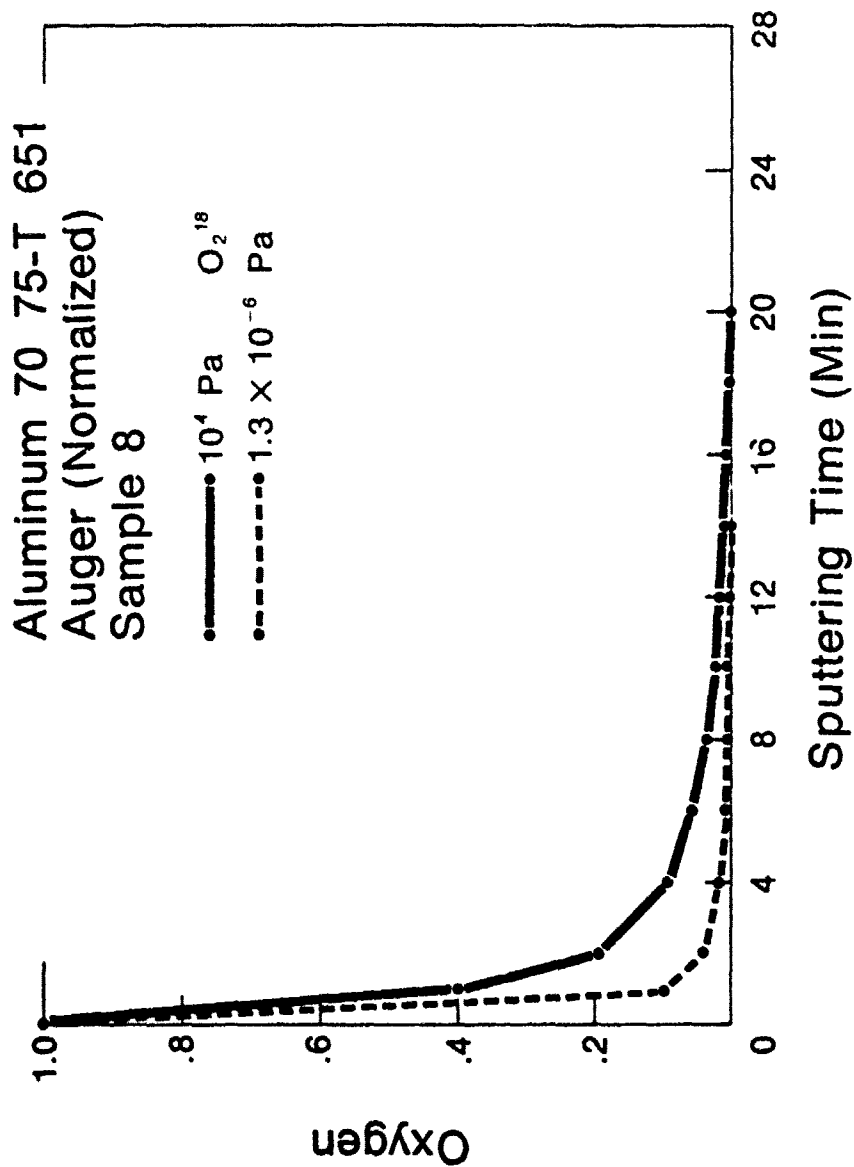

Figure 9. AES Oxygen Profiles From 7075 Aluminum Fatigue Crack Surfaces Formed in Vacuum and Oxygen-18 Environments.

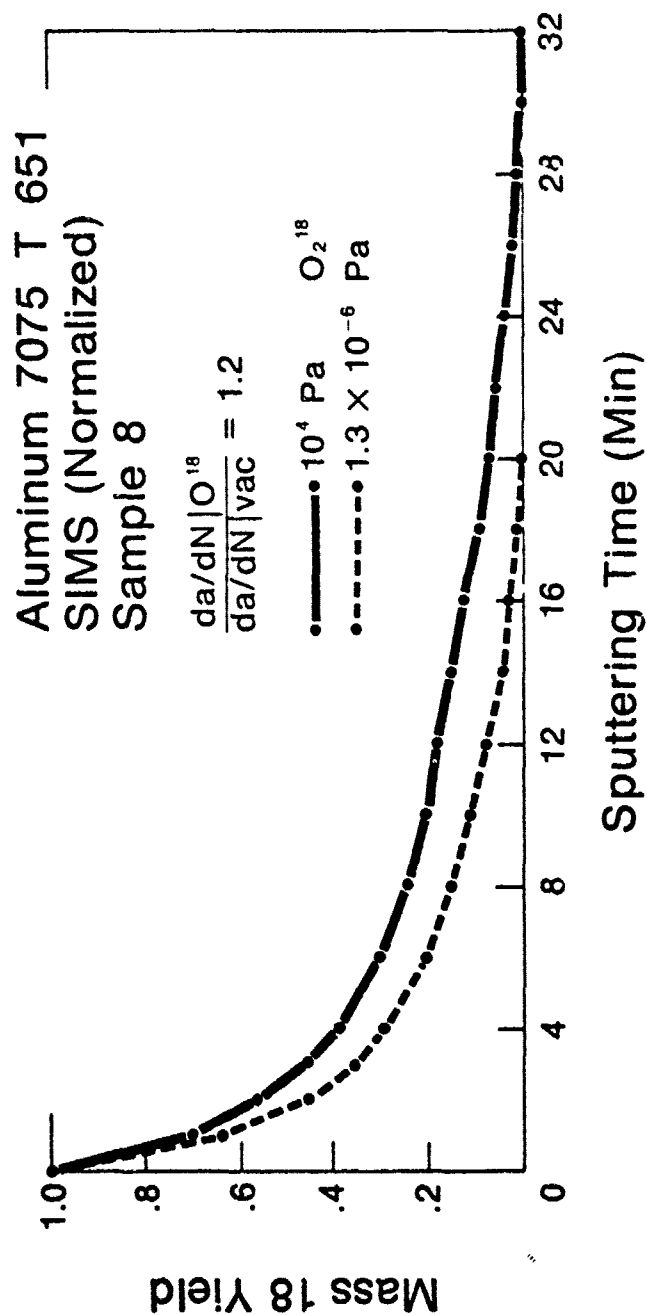

Figure 10. SIMS Oxygen-18 Profiles From 7075 Aluminum Fatigue Crack Surfaces Formed in Vacuum and Oxygen-18 Environments.

As can be seen from Table 3, roughness varied in some cases between samples of the same material for different environments. Due to non-colinearity of the ion beam with the SIMS and the AES optics, results of these techniques can be susceptible to sample roughness variations. For this reason as well as to attempt to get a directly comparable sputtering rate, samples of highly polished Monel and titanium were sputter profiled using identical ion beam parameters as for the fatigue samples. This treatment should produce the same profile as the vacuum fatigue samples, except for any roughness effects, since their normal diffusion controlled oxide thickness should be very close to that of the vacuum sample surfaces. The data showed point by point agreement between the polished and vacuum profiles, in spite of very large roughness differences. This is a strong indication that roughness effects on the data obtained must be minor at most. Since the time used to sputter the polished samples was known, sputter rate calibration could be made directly from the materials under study by determining the depth of the craters sputtered. This was planned, but the interferometer for measuring sputter depths did not become available.

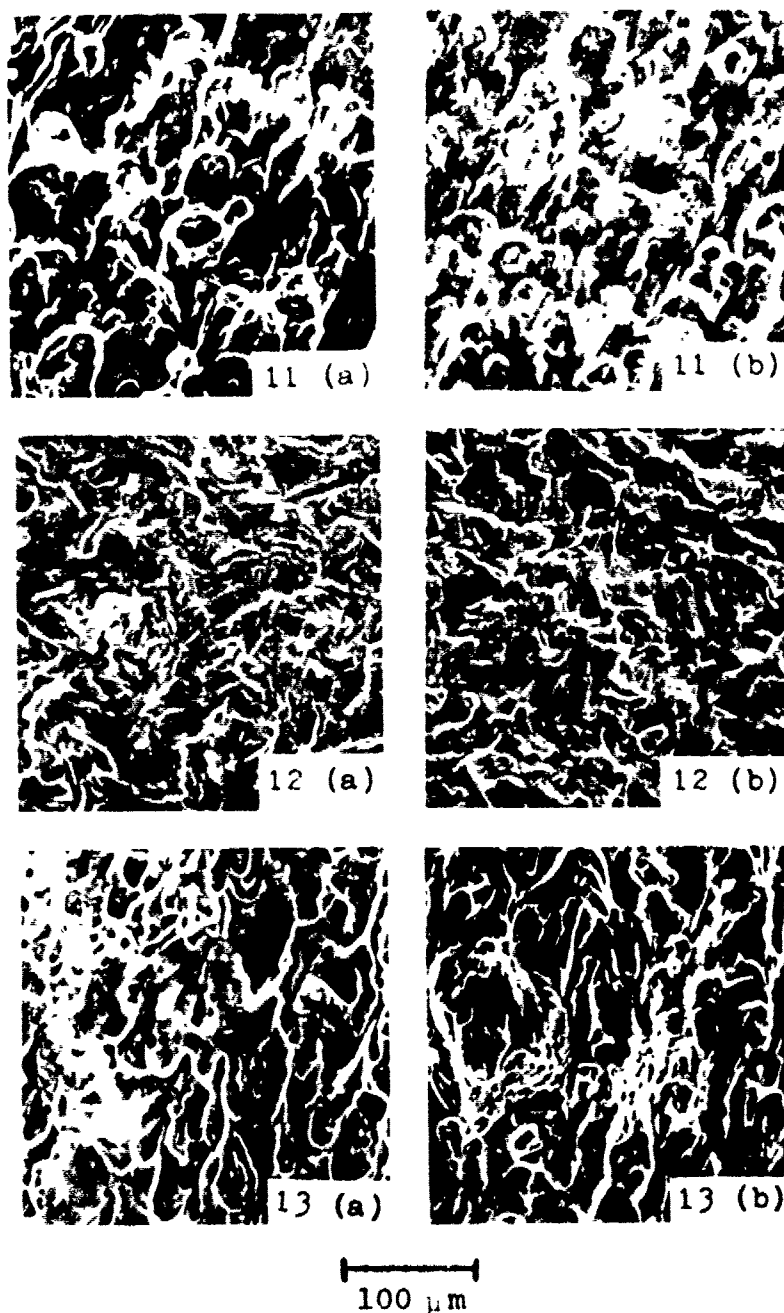

Examination in a scanning electron microscope (SEM) permitted observation of fatigue crack morphology. For

TABLE 3

## RMS Roughness of Fatigue Samples

titanium and the aluminum alloys, no noticeable change in deformation mode due to change in environment is observed (Figures 11 - 13). In addition to the large increase in roughness from earlier results, the Monel 404 surface fatigued in oxygen showed a change in fracture appearance. An indication at the fracture surface of an increase in crystallographic deformation is apparent in Figures 14 and 15 for fatigue of Monel in oxygen, in agreement with [2]. This is consistent with transport by a dislocation mechanism which would be crystallographic in nature. Figure 14(c) provides a comparison of grain size to the fatigue surfaces of Figures 14(a) and (b), while Figure 15 shows comparisons of the two Monel fracture surfaces at higher magnifications. The striations apparent in Figure 15(d) have a width which is approximately the nominal growth increment per cycle.

## CHAPTER IV

### DISCUSSION

Choice of materials for this work was based primarily on oxidation characteristics and oxygen solubility. Since the oxygen transport is expected to be limited to the first few hundred angstroms of fatigue surface, a thick oxide would mask the effect. Monel had the advantage of slow oxidation, improving the chance of measurement of oxygen present due to dislocation transport. Titanium has an oxygen solubility much greater than the other materials tested, about 25 atomic % at room temperature [14]. It was anticipated that this increased solubility might enhance the transport mechanism and produce a more readily detectable indication of sweep-in. Aluminum forms a reasonably thin oxide and the alloys chosen are those of primary interest in on-going fatigue crack growth studies of aluminum alloys.

The raw AES/SIMS data was normalized to indicate oxygen level of one unit at the exterior fatigue crack surfaces. It was observed that the AES profiles leveled off at a value near zero, while the SIMS profiles continued to decrease with sputtering. The rate of decrease in the SIMS signal became very small after a reasonable period of sputtering. The continued gradual

decrease in SIMS signal is believed to be due to cratering of the ion beam and readsorption during sputtering. The point where the AES signal leveled and the SIMS signal had effectively leveled was noted and this signal magnitude was subtracted from the data as background.

There are consistent differences between the AES and SIMS depth profiles with the AES indicating a proportionately deeper enhanced oxygen level when compared to vacuum. Qualitatively, however, there are strong indications of transport in all cases. Sample roughness, residual gases and the shape of the sputtering crater may contribute to the shape of the profiles, the latter being particularly significant in the SIMS results.

One would expect oxidation and diffusion to result in a very sharp, well defined oxide layer followed by a steep oxygen gradient down to the material's solubility limit, particularly for the oxygen-18 since samples were exposed to the isotope only for the short duration of the fatigue tests. The AES profiles indicate such a gradient for oxygen in the vacuum samples, but the SIMS data indicates broadening, or a more gradual decrease in oxygen-18 with depth. For the samples fatigued in oxygen, dislocation transport could result in enhanced oxygen concentration, above the solubility limit, which would result in the observed more gradually decreasing

profile of oxygen. The well-defined oxide thickness is not present in either AES or SIMS profiles because the approximate sputter rate for the ion beam parameters used, as calibrated on  $\text{Ta}_2\text{O}_5$ , was  $70 \text{ \AA}/\text{min}$ . At this rate the expected oxide would be removed very quickly and the profiles would not exhibit the flat surface oxide signal normally expected.

The steady state SIMS levels subtracted from the data were relatively high percentages of the overall signals, while the percentages subtracted from AES were near zero (Table 4). Part of this is due to the cratering effect of the ion beam where new oxide surface is constantly being removed by the low current density outer edges of the ion beam. This is observed only by the SIMS since it sees all of the atoms sputtered off of the surface. The higher spatial resolution AES is not influenced by this problem. It would be expected from the above argument that Monel with its thin oxide layer should be least affected by crater edge broadening in SIMS and it indeed has a low percentage level subtracted.

Readsorption would affect data from AES and SIMS but use of the isotope should reduce the effect for SIMS and the high sputter rate should minimize it for both techniques. It was observed that the background level could be increased by lowering the sputter rate, so

TABLE 4

Percentage of Maximum Signal  
Subtracted from Data as Background

<u>Material</u>	<u>AES</u>		<u>SIMS</u>	
	<u>Vacuum</u>	<u>Oxygen-18</u>	<u>Vacuum</u>	<u>Oxygen-18</u>
Monel	3	10	4	5
Titanium	0	2	18	18
Al 7075-T651	0	37	8	38
Al 2219-T87	0	10	11	29

readsorption was indicated. Residual gases in the chamber during sputtering also contributed to the SIMS signal. It was expected that SIMS's excellent sensitivity in combination with the isotope would yield the best results, however the AES data appears to be less affected by broadening from readsorption, residual gases and crater edge effects.

The broadening problems combined with inaccurate sputter rate calibration prevent detailed quantitative analysis of depth of sweep-in. To estimate sweep-in distance relative to surface oxide thickness it was assumed that the vacuum profile approximates the oxide thickness. The point at which the profiles reach zero is experimentally uncertain so two approximations of oxide thickness were made by noting the sputtering time at which the oxygen signal from the samples fatigued in vacuum reduced to 0.1 and to zero. The same procedure was used on the data for samples fatigued in oxygen. The ratio of sputtering time on oxygen samples to that on vacuum samples should be approximately the same as the ratio of sweep-in depth to surface oxide thickness. An estimate of sweep-in depth can then be made by multiplying these ratios (Table 5) times the expected oxide thickness. As seen from Table 5, the SIMS data and AES data are self-consistent, but each indicates a different depth of

TABLE 5

Ratio of Sputtering Times from Sample Fatigued in Oxygen  
to Sample Fatigued in Vacuum  
at 0.1 of Maximum Level and at Background Sputtering Level

	<u>Monel</u>	<u>Titanium</u>	<u>Al 2219</u>	<u>Al 7075</u>
AES				
	Ratio of Sputtering Times for Signal = 0.1			
	6.3	2.7	5	3.8
SIMS				
	Ratio of Sputtering Times for Signal = 0			
	5.4	2.5	3.7	3
	Ratio of Sputtering Times for Signal = 0.1			
	2	1.7	1.4	1.7
	Ratio of Sputtering Times for Signal = 0			
	2.4	1.6	1	1.5

sweep-in for a given material. Using the AES ratios, which range from about 2.5 to 6, and an estimated oxide thickness of 50 to 100 angstroms, leads to the calculation of sweep-in depths on the order of 125 to 600 Å.

The evidence of this research supports the theory of enhanced transport of oxygen, originating in the gaseous phase, into a metal matrix during fatigue crack propagation. The presently defined model for dislocation transport [7] does not explain the observed enhanced oxygen transport. The use of lattice diffusivity in the model may not be the appropriate value to use in computation of maximum distance of transport possible by dislocations since the lattice in the region of a free surface will be less constrained, which could lead to a higher diffusion rate. It seems unlikely that this could provide the necessary five or six orders of magnitude increase in diffusivity. Although the presently available models of dislocation transport do not explain the results, dislocation sweep-in still is the best candidate to explain the enhanced oxygen transport.

## CHAPTER V

### CONCLUSIONS

1. An increase in growth rate in an oxygen environment as compared to growth rate in vacuum is indicated for Monel 404 and commercially pure titanium. The increase is by a factor of approximately five for Monel and two for titanium. Little increase in growth rate is observed for aluminum 7075-T651 and 2219-T87 alloys.

2. Enhanced concentration of oxygen in the metal matrix due to propagation of a fatigue crack in an oxygen environment compared to a vacuum environment is indicated for Monel 404, commercially pure titanium, aluminum 7075-T651 and aluminum 2219-T87. This is consistent with a dislocation transport mechanism.

3. Comparison of metallurgically polished and fatigue crack surfaces formed in vacuum indicate that sample roughness contributed little error to the measurements.

4. Readsorption during sputtering, residual gases, and inaccurate sputter rate calibration prevent accurate determination of dislocation transport depths, but a rough estimate of  $\sim 125$  to  $600 \text{ \AA}$  is made based on expected oxide thickness.

5. The fracture surfaces from oxygen and vacuum

environments appear the same for each material except Monel 404. In this case fracture surface analysis shows the deformation to have a crystallographic nature for crack growth in the oxygen environment, again consistent with the dislocation sweep-in model.

## VITA

John Wallace Swanson was born in Idaho Falls, Idaho, on December 1, 1947, the son of Winifred and Herbert Swanson. After completing his work at Uvalde High School, Uvalde, Texas, in 1966, he studied for one year at The University of Texas. He accepted an appointment to the United States Air Force Academy, graduating from there in 1971 with a Bachelor of Science degree in engineering mechanics. While serving as an officer in the Air Force, he entered the graduate school of The University of Texas in January, 1976.
